HIGHLIGHTS

- PECVD is a promising technology for depositing APTES.
- A high amine proportion can be obtained by adjusting plasma parameters.
- As-deposited APTES film is in favor of assembling particles at near-nano size.

ABSTRACT

Although solid particles assembling on substrate surface is one of the key points for developing membrane reactors, the technology of organizing nano/near nanometer building blocks into complex structures is still a challenge to scientists in years. In this work, amine functional groups were deposited on the surface of different substrates *via* plasma enhanced chemical vapor deposition (PECVD) technology and (3-aminopropyl)triethoxysilane monomers were used as precursors. The influence of active gas, substrates, as well as deposition time on the physico-chemical features of as-deposited film were investigated, respectively. The highest density of amine of 5.5% on surface was obtained when Ar was utilized as active gas and deposition time was 40 s. Furthermore, Y type zeolite particles at near-nano size were synthesized and subsequently used as a model material for testing the immobilizing ability of plasma treated surface. The results clearly confirmed that a dense mono or multi-layer of closely packed zeolite particles could be formed on the APTES as-deposited surface after 24 h' immersion and the surface area of substrate could be improved by the deposition of zeolite.

1. Introduction

The key point for fabricating catalytic membrane reactors is to functionalize its surface to immobilize packed solid catalyst particles [1–3]. Although the technology of organizing molecules building blocks into complex structures has become common for scientists in recent years. The ability of well-controlling building blocks in bigger size has not yet been acquired. Especially, the catalytic particles with a usual size >100 nm is facing many obstacles for their further application. On one hand, it is difficult to find a suitable functional group with high

attaching ability and good stability; on the other hand, there is still much left for improving the technologies of functionalization. Concerning the variation of raw materials for the fabrication of reactor substrates [4–6], functionalization using organosilane with –NH₂, –SH, –COOH ... are taken into account [7–12]. Especially, (3-aminopropyl)triethoxysilane (APTES) that provides a terminal amine functional group in each molecule was widely used in this decades [11,13–15]. However, the functionalization with APTES is often carried out in a conventional way, which is assistant with a wet-chemistry treatment of surface hydroxylation and ethoxy hydrolysis [16,17], showing many disadvantages: 1)

Fig. 1. The setup of plasma device used in this work.

the treatment method varies from an experimenter to another one, which results in the reduction of the reproducibility; 2) the protocol of treatment usually includes several steps, which means it is time consuming and low efficient; 3) the pretreatment with acids is necessary for activating surface, which would limit the scope of substrate materials; 4) the final surface state of the modified substrate is sensitive and may vary with experimental conditions, e.g. temperature, presence of water, concentration of APTES [18–20].

Alternatively, plasma enhanced chemical vapor deposition method, which is also called PECVD method, is showing promising potential due to its advantages of high reproducibility, high efficiency and low-cost [21,22]. Especially, the plasma deposition process is always accompanied with polymerization [23–25], implying an additional improvement of stability and adhesion strength of organosilane films. In spite that a few papers concerning the functionalization of surface using PECVD method with APTES have been released in recent years [26–32], the characteristics of as-deposited film e.g. the chemical structure, the amine density, etc. corresponding to the plasma parameters like gas selection, deposition time, substrate materials, as well as the ability of APTES layers for anchoring nano/near-nano particles have not been systematically investigated until today.

Zeolite is considered as a specific catalyst of high sharp selectivity in some reactions due to its three-dimensional framework forming channels and/or cages with molecular dimension [33–36]. Besides, its large external surface area provides many reaction sites for heterogeneous catalytic reactions taking place. In other words, zeolite could also be used as a support material that could atomically disperse the other nano catalysts with a high degree of uniformity [37,38]. The utilization of assembled zeolites and/or nano catalysts immobilized zeolites in microfluidic system consisted with the advantages of membrane and microreactor has expanded the applications in heterogeneous catalysis in this decade [39–45]. Recently, zeolite was reported to be used in the investigation of organizing nano to micrometer-sized building blocks on surface [46,47], showing that it could be a model material to test the immobilizing ability of as-functionalized substrates.

In this work, a thin film containing amine groups was deposited by PECVD method with precursor of APTES monomers. In order to maintain amines with high density, the characteristics of as-deposited films were varied by using different gas, substrate and deposition time.

Thereafter, water contact angle meter (WCA), X-ray photoelectron spectroscopy (XPS), Fourier transform infrared (FTIR) spectroscopy and ellipsometry measurements were used for characterizing the surface energy, chemical structure and thickness of as-deposited films. For confirming the immobilizing ability of PECVD treated surfaces, typical catalytic particles (zeolite) at near-nano size were immobilized on the topmost of the substrate surface with as-deposited APTES film.

2. Experimental

2.1. Materials and chemicals

Glass, Cyclic Olefin Copolymer (COC) and silicon were used as substrates with a dimension of 8 mm × 8 mm × 1 mm (3-aminopropyl)triethoxysilane (APTES), carboxyethylsilanetriol sodium (CES) and toluene were purchased from VWR.Co; ethanol and acetone were purchased from Sigma-Aldrich. Ar, O₂ and N₂ gas with a purity of 99.99% were used as active gas for PECVD process.

2.2. Deposition of APTES by PECVD method

A bell type homemade plasma device was used for APTES deposition. The setup of this device was depicted in Fig. 1 and the details was introduced in our previous work [48]. The samples were fixed on the center of a rotating cylinder for deposition. 10 sccm of Ar was initially introduced into the chamber for pretreatment, the samples were activated using a voltage of 20 W under the gas pressure of 0.7 bar for 5 s. Thereafter, the as-activated samples were deposited with APTES for maintaining amine groups. A gaseous mixture consisted with of 20 sccm of active gas (Ar, O₂ or N₂) and 10 sccm of vector gas (Ar) carrying APTES was injected into the reaction chamber. During deposition, the pressure in chamber was fixed at 0.5 mbar and the power was 25 W, the APTES was heated at 80 °C in a gas bubbling tube, the reaction time was varied from 5 s to 80 s.

2.3. Assembling catalytic particles on APTES as-deposited surface

Y type zeolite was used as a model material for the test of immobilizing ability of APTES as-deposited surfaces. The zeolite with a diameter of about 100–150 nm was synthesized according to the method reported by Creaser et al. [49]. Subsequently, 100 mg of as-synthesized Y type zeolite powders and 200 μL of carboxyethylsilanetriol sodium (CES) were magnetically stirred with 30 mL of toluene at 120 °C for 4 h. The as-reacted zeolite powders were repeatedly washed by centrifuge to clean up unreacted CES, and then were dried at 100 °C. Meanwhile, APTES was deposited on COC surface that was deposited with APTES using PECVD. Thereafter, 50 mg of as-dried zeolite powders were magnetically mixed with 20 mL of Millipore water in a beaker, the plasma treated COC were then fixed at the bottom of beaker for 2 min, 10 min, 1.5 h, 3 h, 6 h, 12 h, 24 h and 48 h. During the immersion, the pH value of mixture was adjusted to 8.4. The zeolite deposited COC substrates were then dried at 80 °C.

2.4. Characterizations

A GBX-3S processing system (GBX, France) was used for capturing static water contact angle (WCA) of as-deposited surfaces. In order to test the stability of the APTES films, each sample was rinsed for 30 s by deionized water, dried by compressed air flow and evaluated afterwards. A Tensor 27 spectrometer (Bruker, UK) equipped with a deuterated triglycine sulphate (DTGS) was employed for collecting the Fourier transform infrared (FTIR) spectra, the recording range was from 4000 to 600 cm⁻¹. A PHI 5600-ci XPS spectrometer (Physical Electronics, USA) was used for collecting XPS spectra. For survey spectra, the anode used was a monochromatic Al K α (1486.6 eV) X-ray sources at 200 W. For high resolution spectra, the anode used was a monochromatic Mg K α

Fig. 2. WCA results of glass surface deposited with APTES using different active gas.

(1253.6 eV) X-ray sources at 200 W. Analysis were performed with a 45° angle from the surface. The analyzed surface area was 0.005 cm². Curve fitting for the high resolution C_{1s} core level peaks was done by using the XPS PEAK software (version 4.1) by means of a least square peak fitting procedure using a Gaussian-Lorentzian function (30% Lorentzian) and a Shirley baseline fitting. The quality of the peak syntheses was evaluated by the maximal residual standard deviation (residual STD) method. An analysis was considered significant if the residue was close to unity. On

each sample, three different spots were analyzed. Finally, the binding energy scale was corrected for the neutralizer shift by using the C_{1s} signal from saturated hydrocarbon at 285.0 eV as an internal standard. Depending on the carbon bond and its more or less electron negative partner, the carbon groups were assigned to the corresponding positions. Consequently, the FWHM with consistent value and position constraints were forced for fitting. A UVISEL spectroscopic ellipsometer (Horiba, Japan) was used for the measurement of film thickness from the range of 250–830 nm at an incident angle of 75°.

3. Results and discussion

3.1. Influence of active gas

As the most frequently utilized active gases for plasma deposition [28,29], Ar, O₂ and N₂ were respectively introduced into the chamber when APTES was deposited on glass for 5 s. The WCAs of APTES deposited surface using different active gas are presented in Fig. 2. A significant increase of WCAs was observed after APTES deposition, indicating the chemical structure changes on the topmost of glass substrate. Concerning alkane groups with high hydrophobicity existing in APTES molecule, the increase of WCA could correspond to the successful deposition of films with APTES [50]. Moreover, different active gas showed variation as WCA_{Ar} = 55.9° ± 0.7, WCA_{N₂} = 56.0° ± 1.2 while WCA_{O₂} = 20° ± 2.4. The lower hydrophobic surface is probably due to the oxidation of more alkane groups in O₂ plasma. Furthermore, the stability of as-deposited films were investigated. A tiny change of WCA (<5°) was seen even after 3 times of rinses on each film, confirming a good stability

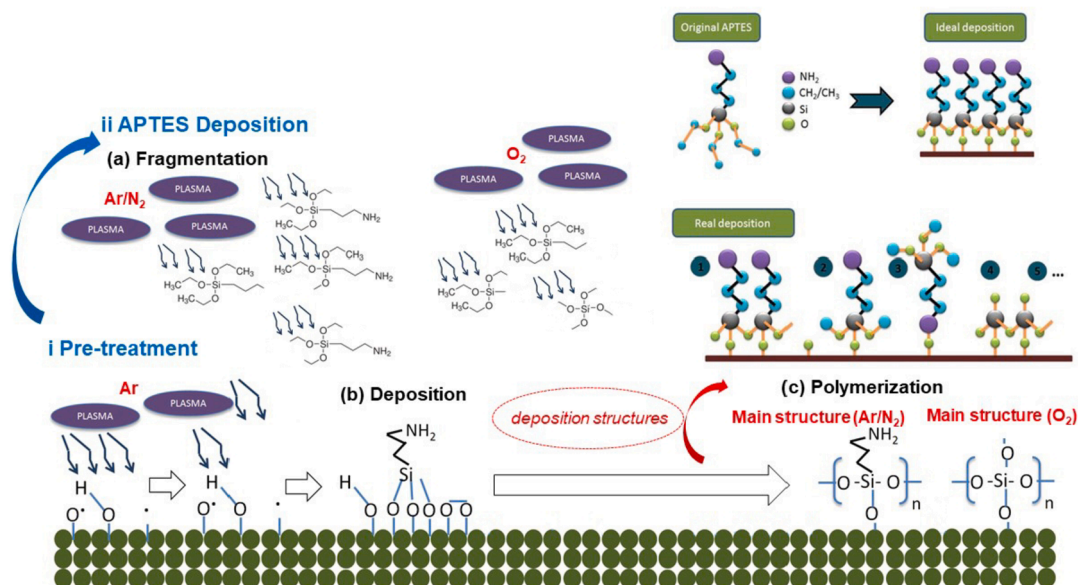

Fig. 4. Mechanism of plasma depositing APTES molecules on surface using different active gas.

resisting water has been achieved during plasma deposition.

The survey scans of APTES deposited surface using different active gas are shown in Fig. 3 and Table 1. The XPS results indicated the changes of chemical composition of films when different active gas was used. The higher contents of nitrogen and carbon, as well as the lower content of oxygen and silicon, were detected from the films deposited in Ar and N₂, respectively, evidencing a successful deposition of APTES on glass surface. In contrast, the high contents of oxygen and silicon, as well as the lower content of nitrogen and carbon were observed from the film deposited in O₂. The surface compositions (see Table 1) between original glass and O₂ plasma treated one were quite similar. As the glass is mainly consisted with SiO₂, it could be related to the formation of SiO₂-like structures in O₂ plasma as a result of oxidizing -CH₂CH₂CH₂-NH₂ and/or -CH₂CH₃ by oxygen radicals [29]. The results were also in accordance with previous WCA measurements, as a lower hydrophobic surface could be achieved due to the formation of more hydrophilic SiO₂-like structures by using O₂.

Interestingly, the films deposited in Ar and N₂ also exhibited higher content of oxygen than that of unreacted APTES (at.%O_{Ar} = 34.5, at.%O_{N₂} = 36.2 vs at.%O_{report} = 21.72 [16]), implying APTES molecules are partially oxidized in Ar or N₂ plasma. Accordingly, the higher O/Si ratios calculated from the films deposited in Ar and N₂ (O/Si_{Ar} = 3.4, O/Si_{N₂} = 4.1 vs O/Si_{unreacted APTES} = 3) were obtained. The oxidation could be attributed to the excitation of residual O₂ by Ar or N₂ plasma. The O/Si ratio of film deposited in O₂ was seen lower than that deposited in N₂ (O/Si_{O₂} = 3.6 vs O/Si_{N₂} = 4.1). However, it is noticed that on one hand the high O/Si ratio corresponds to a higher O content exists in as-deposited film, on the other hand it could also be contributed to a lower Si content. In Table 1, the content of O in the film deposited using O₂ plasma was much higher than that of using N₂ plasma (at.%O_{O₂} = 51.4 vs at.%O_{N₂} = 36.2), while the content of Si in the film deposited using N₂ plasma was much lower than that using O₂ plasma (at.%Si_{N₂} = 8.9 vs at.%Si_{O₂} = 14.3), leading to a lower O/Si ratio of film deposited in O₂. However, higher O and Si contents exist in the film could correspond to the formation of more SiO₂-like structures, in accordance with our speculation. Furthermore, the C/Si and N/Si ratios of films deposited in Ar and N₂ were significantly lower than that of unreacted APTES (C/Si_{Ar} = 4.7 and N/Si_{Ar} = 0.49, C/Si_{N₂} = 4.8 and N/Si_{N₂} = 0.44 vs C/Si_{unreacted APTES} = 9 and N/Si_{unreacted APTES} = 1), indicating a high crosslinking after deposition. It is notice that if a “tripod structure” of APTES, which forms three O-Si-O bonds by losing all the ethoxy groups in molecular, are achieved during deposition, the C/Si

ratio should be 3. The higher C/Si ratio is observed, the more ethoxy groups exist in the film. Thus, the high C/Si ratios indicated that not all the APTES molecules have perfectly bonded to surface through three siloxane bonds in Ar or N₂ plasma. The APTES molecule could lose only one or two ethoxy groups from the three tails; alternatively, it could also keep three ethoxy groups and attach to the surface through the interaction between amine and hydroxyl groups [18]. According to literature [51–54], the organosilanes, as used herein for surface functionalization, are able to polymerize, especially in the presence of plasma, forming a number of possible 2D and 3D surface structures. Thus, APTES molecules deposited on the surface could enable the appearance of various surface structures. It means the APTES film deposited on surface could mainly bind with Si to the substrate and also partially bind with N to the substrate.

The surfaces of substrates are initially pre-treated with Ar plasma. Since the oxygen presents as trace in the reactor is excited by plasma in pre-treatment, the surface is activated with oxygen radicals and hydroxyl radicals. Then APTES monomers are introduced in the chamber and fragmented by plasma. As plasma power is employed, the electric field between electrodes begins to generate free electrons and ions, that are subsequently accelerated leading to collisions with APTES monomer molecules. The monomer molecules are excited to higher energy states, primarily by inelastic collisions with the energetic electrons, and decomposed into fragments (*i.e.* radicals, ions, atoms and more electrons). Thereafter, the fragments of APTES molecules move to the substrate and subsequently bind to the substrate surface through the interaction between ethoxyl group and oxygen/hydroxyl radicals, as shown in Fig. 4. When deposition is processed, APTES fragments continuously bind to each others and form an amorphous polymerized film [21,28]. However different active gas could lead to the formation of different layers: deposition in Ar or N₂ plasma forms a layer with the similar chemical structure that corresponds to the feature of APTES, which could be contributed to that argon and nitrogen radicals are not reactive species for organosilanes. As the binding energy of chemical chains of APTES molecule varies [55], APTES monomers are fragmented into various forms. Thus, the as-deposited layer should be consisted with different APTES structures [56,57]. When Ar or N₂ is used, the as-deposited film is consisted with major APTES-like structures (Fig. 4 ②③) and minor SiO₂-like structure (Fig. 4 ④). When O₂ is used, the as-deposited film is consisted with major SiO₂-like structure (Fig. 4 ①) and minor APTES-like structures (Fig. 4 ②③).

The high resolution C_{1s} spectra of APTES deposited surface using

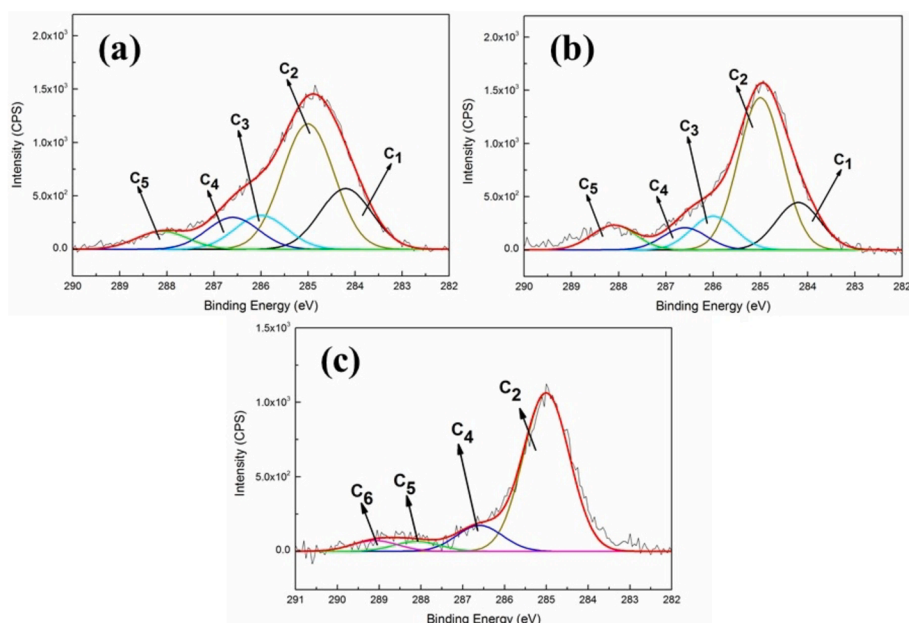

Fig. 5. High-resolution XPS spectra of glass surface deposited with APTES using different active gas: (a) Ar, (b) N₂, (c) O₂.

Table 2

Relative contribution of the deconvoluted components of the C_{1s} peaks.

Active gas	C _{1s}						Amine (Relative to total composition, %)
	C ₁ (%)	C ₂ (%)	C ₃ (%)	C ₄ (%)	C ₅ (%)	C ₆ (%)	
Ar	20.1	53.0	10.4	11.5	5.0	–	5.0
N ₂	13.3	63.7	9.3	7	6.7	–	3.9
O ₂	–	82.8	–	7.8	2.6	6.8	–

different active gas are shown in Fig. 5. As seen in Fig. 5(a) and (b), C_{1s} spectra obtained from the films deposited in Ar and N₂ could be deconvoluted into five peaks: a peak centered at 285.0 eV (C₂) corresponding to C–C, C=C and C–H groups; a lower binding energy (BE) peak centered at 284.2 eV (C₁) corresponding to C–Si; three higher BE peaks centered at 286 eV (C₃) 286.6 eV (C₄) and 288.1 eV (C₅), corresponding to C–N, C–O/C=N and N–C=O/C=O groups, respectively. The results are in accordance with that of as-reported APTES films [27]. Differently, the sample that acquired in O₂ plasma shows only C₂, C₄ and C₅ components with an absence of C₁ peak relating to C–Si groups and C₃ peak relating to C–N groups, indicating the oxidation of –CH₂CH₂CH₂NH₂ and –CH₂CH₃ when O₂ is used. Concerning there's still high content of silicon existing in the film, it could be reasonably speculated that Si–CH₂CH₂CH₂NH₂ and Si–CH₂CH₃ have been oxidized and transformed into SiO₂-like structure in O₂ plasma [29]. A new peak centered at 289.2 eV corresponding to O–C=O groups (C₆) was observed in this spectrum. It could also be attributed to the strong oxidation in O₂ plasma. Based on the components proportion in C_{1s} (Table 2), the real proportion of C–N bond (C₃) in the film can be calculated using Equation (1):

$$\%_{C-N \text{ in coating}} = C_{1s} \times \%_{C_3} \quad (1)$$

where C_{1s} is the content of carbon in film, %C₃ is the proportion of C₃ bond in C_{1s}. Thus, the results indicated that Ar is the better active gas for obtaining amine groups (C–N_{Ar} = 5.0% vs C–N_{N₂} = 3.9%).

3.2. Influence of substrate

Three typical raw materials (glass, COC and Si) for fabricating membrane reactor were investigated, Ar was used as active gas and the

Fig. 6. WCA measurements of APTES film deposited on glass, COC and silicon.

deposition time was fixed at 40 s. WCA results presented in Fig. 6 indicated the similar hydrophilicity was achieved on different substrates. Furthermore, the similar stability resisting water of all the samples implied that the nature of substrates is not a key factor to affect the films's chemical properties.

FTIR spectra of APTES film deposited on different substrates showed the similar feature (Fig. 7). A strong absorption band at about 1050 cm⁻¹, corresponding to Si–O–C and Si–O–Si, could contribute to polymerized or physisorbed APTES molecules. Another band at the shoulder of 1150 cm⁻¹ was probably due to short chain Si–O–Si as a result of cross-linking [58], while the band around 1050 cm⁻¹ was assigned to the long chain Si–O–Si [29,30,48]. The bands corresponding to primary amine appeared in the range of 1400–1700 cm⁻¹: two vibrational modes at 1620 cm⁻¹ and 1400 cm⁻¹ were due to NH₂ group from APTES [21,23] and C–N bonds from amines or amides [29], respectively. The absorption band at 1750 cm⁻¹ relating to C=O groups was also an evidence of amides. Thus, it indicated the oxidation of the amines to amide by residual oxygen radical during deposition. The asymmetric and symmetric deformation modes corresponding to CH₂ and CH₃ groups of ethoxy were seen around 2950 and 2870 cm⁻¹,

showing the existence of unhydrolyzed APTES. Moreover, the broad absorption band in the range of 3400–3250 cm^{-1} could also be assigned to the OH stretching of H_2O or symmetric/asymmetric NH stretching modes of APTES.

Furthermore, the elemental compositions of films deposited on various substrates determined by XPS are shown in Table 3. The APTES films deposited on glass and COC presented similar O/Si, C/Si and N/Si ratio, indicating the same chemical structure are formed on both

Deposition time (s)	Thickness (nm)	Water contact angle on different substrates (°)		
		Glass	COC	Si
5	7.7 ± 4	55.9 ± 0.7	50.9 ± 1.0	54.3 ± 0.6
14	25.3 ± 4	37.7 ± 1.7	39.9 ± 0.8	39.4 ± 0.5
40	82.4 ± 8	31.3 ± 1.9	33.2 ± 0.7	37.2 ± 1.0
80	150.1 ± 7	40.6 ± 0.5	49.3 ± 0.7	43.8 ± 1.0

substrates. The different ratios of O/Si, C/Si and N/Si acquired from Si surface are probably due to the contamination of the gas phase by etched silicon atoms from substrate. The further high resolution C_{1s} spectra confirmed the speculation as the same deconvoluted components with similar proportion are maintained from the three substrate surfaces. (cf. Fig. 8 and Table 4). All the results clearly indicated that plasma

polymerization leads to an efficient APTES deposition on all the substrates that are potential materials for reactor fabrication. Furthermore, similar amine contributions were obtained from the film on different substrates (%Amine_{glass} = 5.5, %Amine_{COC} = 5.7, %Amine_{Si} = 5.5). If we consider the chemical structure of APTES, the hydrophilicity is mainly controlled by the amine group and the density of amine on the surface determines the WCA on surface. Thus, no obvious change of hydrophilicity could be detected on various substrates in Fig. 6, in accordance with XPS results.

3.3. Influence of deposition time

As shown in Fig. 9 and Table 5, the film thickness changed as the deposition time varied during 5–80 s and the average growth rate was about 1.9 nm/s. The WCAs on three different substrates showed the similar trend of change: WCAs decreased during 5–40 s and then followed by a slight increase. It is known to all, the number of active species generated from precursor molecules increases with a raise of deposition time. Thus, the more amine groups are obtained with an increase of time. However, the longer time also increases the risk that as-deposited film exposes to plasma, which subsequently leads to bombardment of the reactive polar groups. Finally, the over-treatment of film changes the polarity of molecules and causes the increase of WCAs on surface.

The FTIR spectra of APTES films deposited on COC using different time presented in Fig. 10 highlighted the changes of chemical bonds. As a result of improving film thickness, the peak in the range of 3400–3250 cm⁻¹ corresponding to the symmetrical/asymmetrical NH stretch modes increased with a raise of deposition time (Fig. 10(a)). However, the intensity of peak at 1750 cm⁻¹ relating to carboxylate functions showed different trend (Fig. 10(b)):

$$I(\text{C}=\text{O})_{5\text{s}} < I(\text{C}=\text{O})_{80\text{s}} < I(\text{C}=\text{O})_{14\text{s}} < I(\text{C}=\text{O})_{40\text{s}}$$

Besides, the peaks in the range of 1650–1590 cm⁻¹ were attributed to N–H bending (scissoring) vibration of primary amines [59]. Interestingly, an increase of peak intensity as well as peak center shifting to higher frequency with a raise of deposition time was observed, indicating the increase of the free amine transformed from H-bonded amine [21,60]. When the deposition time was extended to 80s, the peak center shifted to 1660 cm⁻¹. The band could be assigned to the vibrational mode of amide/imine/oxime, which is probably due to the intensive oxidation induced by long time exposure to plasma [29,58].

Furthermore, the XPS analyses were performed and the results are shown in Table 6. The content of carbon decreased with an increase of nitrogen, indicating the formation of a more inorganic film by increasing deposition time. The highest C/Si ratio and the lowest N/Si ratio were obtained when the deposition time was 5 s, indicating an insufficient polymerization. The results suggested the deposition time for APTES in our system should be longer than 5 s.

Table 7
Relative contribution of the deconvoluted components of the C_{1s} peaks.

Deposition time (s)	C _{1s}					Amine (Relative to total composition, %)
	C ₁ (%)	C ₂ (%)	C ₃ (%)	C ₄ (%)	C ₅ (%)	
5	20.1	53.0	10.4	11.5	5.0	5.0
14	21.9	49.1	12.4	7.9	8.7	5.3
40	23.2	44.8	12.7	8.7	10.5	5.5
80	23.4	47.1	11.3	10.2	8.0	4.8

The proportions of each components contributed in C_{1s} spectrum as a function of deposition time are shown in Table 7. A sharp decrease of C–O/C=N content (C₄) was seen when deposition time was longer than 5 s. It could be contributed to Si–O–CH₂CH₃ of APTES forming siloxane bond, evidencing more crosslinking occurs after 5 s. Thereafter, C–O content increased with a raise of deposition time during 14–80 s, indicating an increase of imine or oxime. The C=O content (C₅) increased with a raise of deposition time. However, a strong decline was seen after 40 s. All the results were in accordance with the FTIR spectra as shown in

Fig. 9(b). The highest C–N content (5.5%) in film was obtained when the deposition time was 40 s.

In order to confirm the high efficiency of using plasma method, the glass substrates were functionalized with APTES in a wet-chemistry way [61]. The results of survey scan, high-resolution spectrum and contribution of each component are shown in Fig. 11. Base on these results, the real proportion of C–N bond (C₃) in the film corresponding to amine density could be calculated. The amine density obtained by wet-chemical treatment was about 3.6%. Thus, the density of amine deposited using plasma was obviously higher than that of using wet-chemistry (%Amine_{plasma} = 5.5 vs %Amine_{wet-chemistry} = 3.6) in this work. Furthermore, a decrease of C–N content was seen as the deposition time was 80 s. The longer deposition time could rise the risk of exposing topmost of as-formed film to plasma, and subsequent leads to a functional change of film [58]. Thus, the deposition time is suggested to be in the range of 14–40s, in accordance of FTIR results.

3.4. Particles anchoring on APTES as-deposited surfaces

In order to estimate the potential of APTES deposited surface for

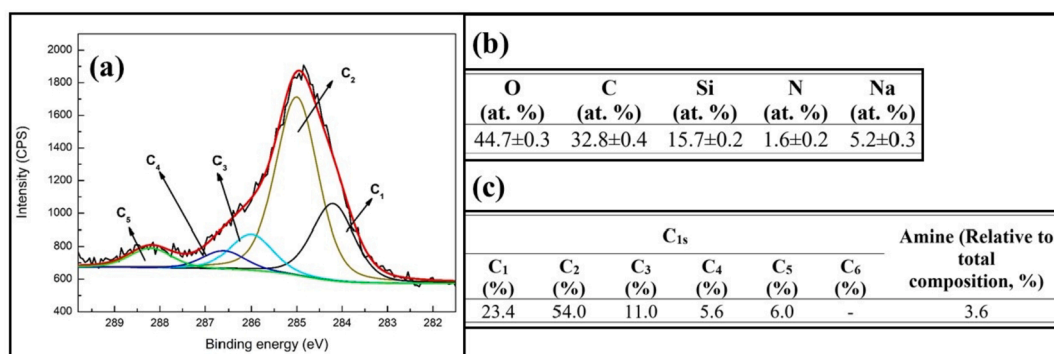

Fig. 11. (a) High-resolution C_{1s} XPS spectrum of glass surface deposited with APTES using wet-chemical treatment; (b) XPS measurements of glass surface deposited with APTES using wet-chemical treatment; (c) relative contribution of the deconvoluted components of the C_{1s} peaks.

Fig. 12. The process of immobilizing zeolite on APTES deposited surface.

Fig. 13. Morphology of COC surface immobilized with Y zeolite using different immersion duration.

making membrane reactors, Y type zeolites were used as a model material and were immobilized on the COC surface deposited with APTES (active gas: Ar, deposition time: 40 s). Carboxyethylsilanetriol sodium (CES) has been reported a promising linkage reagent as the uniform carboxylate group distributions on surface could endow high negative charges density at some pH value [62]. As presented in Fig. 12, zeolite particles were functionalized using CES in our work; meanwhile COC substrate was plasma polymerized with APTES for endowing amine groups on its surface. Based on the $pK_{aCOOH} = 2.5$ and $pK_{aNH_2} = 10.6$, massive $-COO^-$ and $-NH_3^+$ were respectively generated on the surface of zeolite and COC in a suspension of $pH = 8.4$. Thereafter, zeolite particles were immobilized on COC surface through the $-NH_3^+/-COO^-$ zwitterionic pairs [63].

As presented in Fig. 13, the degree of zeolite coverage varied from very scarce to very dense. In the early immersion period of 2–10 min, a few particles appeared on surface with very low coverage, indicating the seeding procedure occurs and the number of seeded zeolite particle raises with increasing time. As the immersion duration was extended to 1.5–3 h, the as-seeded zeolite particles tended to attach free zeolite particles in suspension, forming closely packed island-like precipitants. Meanwhile, as-deposited zeolites migrated and assembled on the surface, forming the same structure. Then the closely pack precipitants grew with an increase of immersion duration of 6–12 h. Finally, the surface was fully covered by a dense coating consisted with packed zeolite particles after 24 h's immersion. Furthermore, the longer immersion duration of 48 h showed little difference, suggesting 48 h's immersion is in favor of forming a multilayer, while 24 h's immersion is suitable for fabricating a monolayer.

FTIR spectra of zeolite immobilized surfaces treated using different immersion duration are shown in Fig. 14(a). A band corresponding to Si–O in SiO_4 tetrahedron was obtained from all the samples, indicating the existence of zeolites. XPS spectrum of Y zeolite immobilized surface immersed for 24 h is presented in Fig. 14(b). In comparison of APTES as-

deposited surface, characteristic peaks relating to Na_{1s} , Al_{2s} and Al_{2p} , as well as the increase of Si_{2s} and Si_{2p} peak intensity were seen, confirming the successful immobilization of zeolites, in agreement with FTIR results. Moreover, the variation of FTIR evidenced the increase of zeolite with a raise of immersion duration from 2 min to 48 h, as the improvement of Si–O band was observed. The higher intensity of Si–O peak obtained using 48 h's immersion, implied the increase of zeolite coating thickness due to the formation of multilayer.

A comparison experiment was carried out by immobilizing zeolite on the surfaces that were deposited with APTES and without APTES (immersion time: 48 h). The morphology of different surfaces are shown in Fig. 15. It was obviously seen that the feature of COC surface had been totally changed and the roughness of surface increased after immobilizing zeolite on APTES deposited surface, indicating an enhancement of surface area. The increase of surface area suggested that zeolite immobilized surface could be used for improving catalytic performance of membrane reactors or microreactors in dynamic solvents [1–3,13].

4. Conclusion

Thin polymerized films with high density of amine functional groups were deposited on surface using a PECVD method with APTES precursors. The films on various substrates showed similar chemical

structure related to APTES, evidencing that PECVD was a universal method for depositing APTES regardless of substrate nature. O₂ was confirmed a negative active gas for APTES plasma deposition, as massive SiO₂-like structures were generated by oxygen radicals. In comparison of N₂, amines deposited in Ar showed the higher density. Furthermore, The results showed the change of film characteristics with increasing deposition time. In order to avoid long exposure time to plasma, the deposition time should not be longer than 40 s. Under the conditions of Q_{APTES} = 10 sccm, Q_{Ar} = 20 sccm, P = 25 W, p = 0.5 mbar, t = 40 s, the maximum amine proportion of 5.5% was obtained in this work. Y type zeolite particles at near-nano size were then immobilized on the APTES deposited surface using different immersion duration (2 min–48 h), and the results proved plasma deposited amine was in favor of assembling near-nano particles, as a dense mono or multi-layer consisted with packed zeolites was detected after 24 h's immersion. The increase of surface area on APTES deposited COC substrate suggested that zeolite immobilized surface could be used for improving catalytic performance of membrane reactors or microreactors in the future.
